

Patriotism and the Choice Process: National Pride After 9/11

Omar Lizardo

UCLA

July 8, 2026

Abstract

Which groups are more likely to experience increased feelings of national pride after the experience of a threat to the nation? Using survey data on a representative sample of Americans collected before and after the events of 9/11, this paper adjudicates between competing hypotheses regarding the socio-demographic distribution of national pride. Theories of “irrational conservatism” and needs-based attachments predict that lower-status individuals will experience the largest increase in national pride. In contrast, the choice-process approach suggests that higher-status individuals—who experience greater autonomy and are more likely to be embedded in nested voluntary associations—will be more likely to increase their affective attachment to the national collectivity under a “distal” attribution rule. Results from the General Social Survey (1996 and 2004) support the choice-process theory, demonstrating that educated individuals and members of specific nested subgroups experienced the most significant increases in national pride post-9/11.

1 Introduction

Which groups are more likely to experience increased feelings of national pride after the experience of a threat to the nation? In this paper, I use survey data on a representative sample of Americans collected before and after the events of 9/11 to shed light on this question. This “natural experiment” allows me to adjudicate between competing hypotheses regarding the socio-demographic distribution of feelings of national pride following a threat to the nation.

Theories in the tradition of the “authoritarian personality” ([Adorno et al., 1950](#)) and the modern political science of the personality correlates of political ideology ([Jost et al., 2007, 2017, 2008](#)) conceive of national pride as reflecting a form of “irrational conservatism,” driven by fundamentally ingrained motivational and affective factors that differ across people. These theories predict that members of low-status groups will be much more likely to experience renewed feelings of national pride after experiencing a threat to the nation. From this perspective, a threat to the nation is seen as endangering the “ontological security” ([Giddens, 1984](#)) of persons whose lives are characterized by routine and alienating work, who are disengaged from established institutions, or who have been left behind by recent structural changes to the economy and rapid cultural shifts in dominant values ([Wuthnow, 2019](#)).

Theories of attachment to collectivities as a nested group ([Lawler, 1992; Mueller and Lawler, 1999](#)), on the other hand, point to a different dynamic and lead to a clearly divergent empirical implication. According to the choice-process approach, individuals are more likely to experience affective attachment to a larger group within which other groups that they belong to are nested (such as the nation), *only* to the extent that they are able to in fact experience freedom and autonomy in their everyday dealings, and to the extent that this autonomy and freedom is *attributed* to membership both in the more proximate groups that they are part of, and to the larger unit within which these groups are nested.

These two propositions suggest that, given that high status individuals are more likely to be in structural positions that afford autonomy and self-direction ([Kohn and Schooler,](#)

1969; Kohn, 1977; Kohn and Schooler, 1978), and given that they are more likely to belong to “nested-subgroups,” such as voluntary associations (Bell and Force, 1956; Freeman et al., 1957; Janoski and Wilson, 1996; Knoke, 1986; McPherson, 1981; Scott, 1957; Tomeh, 1973; Dederichs, 2024), within which feelings of attachment to super-ordinate collectivities can be fostered and made salient, the choice-process theory predicts that it will be high-status individuals who will be more likely to experience renewed feelings of national pride following a threat to the nation.

In this paper,

2 Where Does National Pride Come From? Two Approaches

2.1 The Needs-Based and Irrational Conservatism Models

Standard approaches in social psychology geared toward explaining individual differences in affective attachment to nations as collectivities usually point to factors associated with the emotional needs that such feelings of national pride meet (Jost et al., 2007). Thus, classic studies of the authoritarian personality noted how persons who scored high on authoritarianism scales were also prone to express “irrational” feelings of pride and “blind” attachment to the nation conceived as a solidary collectivity (Adorno et al., 1950; Pettigrew, 1999). Excessive attachment to national groups is usually regarded as pathological and as leading to various suboptimal societal outcomes, such as support for authoritarian or charismatic leaders and less support for democratic or inclusive institutions (Santos and Jost, 2024).¹

If feelings of national pride are an expression of either authoritarianism or irrational

¹Social Identity Theory and Self-Categorization Theory can also be considered “need-based” theories (Hogg and Terry, 2000). In these frameworks, the self-enhancement motive leads individuals to become affectively attached to prestigious national collectivities. Individuals become attached to national groups in the very same way that they become attached to any other group—if the group is perceived as meeting emotional needs for self-esteem, prestige, and a sense of efficacy and belonging.

conservatism, then we should find it overrepresented among those groups marked by the socio-demographic characteristics typically associated with these cognitive and affective orientations. The bulk of the research suggests this refers to low-status, low-education groups, typically alienated from mainstream institutions and disempowered in their everyday interactions (Collins, 1986; Jost, 2017; Jost et al., 2003). This implies that post-9/11 increases in national affective attachment in the U.S. should be concentrated among lower-status groups, who may be more likely to react to epistemic and existential threats to the status quo by becoming affectively attached to the nation, thereby increasing their belief in the propriety and desirability of existing systems.

2.2 Lawler’s Choice-Process Theory and Nested Attachments

In contrast to needs-based and irrational conservatism views, Edward Lawler’s (1992) choice-process theory posits a different mechanism. According to the theory, people value individuality, freedom, and self-efficacy, and they engage in structured action within concrete social contexts, primarily nested subgroups, to enact those values. In this way, groups provide individuals with a “context of choice” within which successful purposive action occurs. Positive emotions stemming from the sense of autonomy and control afforded by the group trigger an attribution process that leads people to become affectively attached to those groups and, by implication, to any larger group within which those groups are nested.

From this perspective, national “groups”—closer to “imagined communities” in Anderson’s (1991) sense—will be the object of strong positive affective attachments to the extent that they are perceived as responsible for giving the person a sense of autonomy, freedom, and a structured “menu” of choices. The central point is that emotions produced in choice processes help account for actors’ affective attachments to multiple, nested collectivities of which they are members. Under normal circumstances in individualistic societies like the United States, a *proximal rule* prevails: local groups tend to elicit stronger feelings of attachment than more distal groups within which they are nested (e.g., cities, states, the U.S. as a whole).

However, when the individual is embedded in nested groups that allow for the transfer of positive affect from smaller to larger collectivities, the nation can become the beneficiary of this affective attachment if attribution rules shift.

2.3 The Theoretical Status of 9/11: A Shift in Attribution Rules

From both the need-based and irrational conservatism perspectives, 9/11 is seen as an external “shock” that increases ingroup-outgroup differentiation, leads to processes of self-categorization, and results in more intense feelings of affective attachment to the collectivity, particularly among those with presumably the largest psychological needs (e.g., to justify the system, need for order and cognitive closure, and so forth). From the choice-process perspective, on the other hand, 9/11 can be seen as a shock to the *cultural rules* that govern the attribution of responsibility for the positive feelings engendered by the choice process. In the immediate post-9/11 period, we should expect a weakening of the proximal rule and the emergence of a *distal rule*. Under a distal responsibility regime, the nation becomes more salient as the ultimate source of opportunities for choice, freedom of expression, and autonomy.

This sense of saliency should be stronger for individuals embedded in nested subgroups. Therefore, efficacious action in structured social arenas and embeddedness in nested subgroups should be positively connected to affective attachment to the national collectivity when the proximal rule is weakened. Consequently, post-9/11 increases in national affective attachment should be concentrated among high-SES individuals, who are more likely to engage in high autonomy everyday behavior and more likely to belong to multiple nested subgroups.

3 Data and Variables

To adjudicate between these hypotheses, I rely on data from the 1996 and 2004 waves of the General Social Survey (GSS). These two waves, collected before and after the events of September 11, 2001, include a special module on attitudes toward the United States, providing an ideal natural experiment to assess shifts in national attachment.

3.1 Dependent Variables

Two primary dependent variables are analyzed: a U.S. Pride scale and a Nationalism scale. The U.S. Pride scale is an additive index constructed from ten questions asking respondents how proud they are of America across various domains. The prompt asks, “How proud are you of America in each of the following...” followed by domains such as the way democracy works, its political influence, economic achievements, social security system, scientific and technological achievements, sports, arts and literature, armed forces, history, and fair treatment of groups. Response categories are “Very proud,” “Somewhat proud,” “Not very proud,” and “Not proud at all.” Each item was dichotomized so that “Very proud” equals 1 and all other responses equal 0, yielding an additive scale from 0 to 10 (Cronbach’s $\alpha = 0.80$).

The Nationalism scale captures agreement with statements asserting American superiority and blind loyalty (Schatz et al., 1999). It is computed as the mean of four items: (1) “I would rather be a citizen of America than of any other country in the world,” (2) “The world would be a better place if people from other countries were more like the Americans,” (3) “Generally speaking, America is a better country than most other countries,” and (4) “People should support their country even if the country is in the wrong.” Responses were recorded on a 5-point Likert scale ranging from “Strongly agree” (1) to “Strongly disagree” (5). The items were reverse-coded prior to averaging so that higher values indicate stronger nationalism (Cronbach’s $\alpha = 0.64$).

3.2 Independent Variables

The primary independent variables of interest are education and embeddedness in nested subgroups (voluntary associations). Education is measured continuously as the highest year of school completed (ranging from 0 to 20).

To evaluate nested subgroup embeddedness, I utilize data on voluntary association memberships available in the 2004 wave. Respondents were asked whether they belonged to any of 15 different types of groups (e.g., fraternal, service, veterans, political, labor union, sports, youth, school, hobby, school fraternity/sorority, nationality, farm, literary/art, professional, and church-affiliated groups). Each membership type is represented as a binary indicator (1 = Yes, 0 = No). I also calculate the total number of memberships per respondent to capture overall associational embeddedness.

3.3 Control Variables

All models include statistical controls for birth cohort (centered at 1955). The 2004 cross-sectional models additionally control for gender, race, and geographic region. While political ideology is theoretically relevant, it cannot be included in the main models due to a severe data availability issue: in the 2004 GSS wave, the questions assessing political ideology and the module assessing national attachment were administered on mutually exclusive ballots, resulting in no respondents having data for both variables in that year. We therefore exclude it from our primary analyses to allow for the 1996-2004 comparison. However, Appendix A presents supplementary models adjusting for political ideology restricted to the 1996 subsample for which this data is available.

4 Results

4.1 The Period Effect on Pride Items

An initial examination of the binary items comprising the U.S. Pride scale confirms a substantial period effect between 1996 and 2004. Survey-weighted logistic regressions indicate that the likelihood of respondents reporting being “very proud” of the United States significantly increased across nearly all measured domains (see Figure 1). Not surprisingly, pride in America’s armed forces is an outlier, but we can also observe notable increases in pride for U.S. history, fair treatment of all groups, arts and literature, and economic achievements post-9/11. These universal shifts across items mean that the overall distribution of the U.S. Pride scale shifted markedly upward in 2004 compared to 1996 (see Figure 2).

Figure 1: Increase in Likelihood of Being ‘Very Proud’ Post-9/11 (Odds Ratios)

Figure 2: Distribution of U.S. Pride Scale Scores (1996 vs. 2004)

4.2 Nationalism and Irrational Conservatism

The irrational conservatism perspective predicts that 9/11 should have driven an increase in nationalism, particularly among lower-status and less-educated groups. However, our baseline and interaction models assessing the Nationalism scale yield a different picture. While baseline nationalism was indeed higher among older individuals with lower levels of educational attainment in 1996 (Jost et al., 2003), the interaction between education and the survey year on the Nationalism scale is neither statistically nor substantively significant. The need-based and irrational conservatism hypotheses fail to fully capture the changing dynamics of national attachment after 9/11, as the anticipated surge in blindly patriotic nationalism among the dispossessed did not neatly materialize as the primary driver of the 9/11 effect (Table 2).

4.3 Education and the 9/11 Effect

Turning to the U.S. Pride scale under the Choice-Process framework, we compare the effects of education across the two periods. OLS models reveal a striking reversal. In 1996, education was weakly, and sometimes slightly, negatively associated with national pride. However, in 2004, the effect became positive and significant. A pooled model that formally tests the interaction between education and the survey year confirms a significant positive interaction term. Higher levels of education were strongly associated with increased national pride *after* 9/11. This shift directly supports the choice-process prediction: individuals with greater structural autonomy experienced the most dramatic increase in their national attachment patterns under the new distal attribution regime. Table 3 presents the regression models showing this interaction, and Figure 3 plots the marginal effects, clearly demonstrating the steeper slope of education in 2004.

4.4 Nested Membership and National Attachment

Following the choice-process framework, we assess how voluntary association membership acts as a nested grouping structure that correlates with attachment to the nation using the 2004 sample. A crucial dynamic emerges when disaggregating organizational memberships. While the overall sheer volume of voluntary memberships does not unilaterally drive national pride, specific *types* of organizational memberships have strong, distinct effects.

According to choice-process theory, affective attachment to the nation requires that the proximate group be cognitively nested within the national structure. Our results confirm this: groups that are inherently linked to the national fabric—such as Veterans Groups, Political Clubs, and Fraternal Organizations—foster autonomy that is easily attributed to the larger national collective, resulting in significantly increased U.S. pride. When memberships are merely aggregated into a total count, the positive effects of these highly-nested groups are diluted by the noise of locally-focused or apolitical associations (see Table 4 and Figure 4).

Figure 4: Effect of Specific Association Memberships on U.S. Pride (Controlling for Cohort)

5 Discussion and Conclusion

After the traumatic events of 9/11, the United States appears to have switched from a “local” (proximal) to a “national” (distal) affective attachment rule. Standard psychological perspectives on nationalism fall short in predicting *which* individuals were more likely to experience national pride in this new period. Needs-based approaches predict that those with the most dire needs for belongingness (low-status groups) should increase their attachment, while irrational conservatism approaches expect those with high initial levels of

ethnocentrism to drive the shift. Neither is the case.

Instead, the results are consistent with the implications of the choice-process approach. Post-9/11, it was precisely those individuals more likely to experience autonomy in their day-to-day behavior—the highly educated—who increased their attachment to the national collectivity. Furthermore, embeddedness in specific nested groups accounts for how the positive affect generated in local, structured contexts is transferred to the nation.

An important analytical distinction must be maintained between class-based *expression rules* and *feeling rules*. While lower-status individuals may be more likely to *express* national pride (e.g., via bumper stickers or overt patriotic displays), they were paradoxically less likely as a group to experience a proportional *increase* in affective attachment. High-status individuals embedded in nested groups were actually more likely to *feel* increased national pride after 9/11, even if they were less likely to outwardly express it in stereotypical ways. By shifting our theoretical lens to the choice process, we can better understand the structural and affective foundations of modern patriotism.

A Supplementary Models with Political Ideology (1996 Only)

Because the 2004 GSS administered the political ideology and national attachment modules on mutually exclusive survey ballots, it is impossible to adjust for political ideology in pooled models or models using the 2004 sample. However, given the theoretical relevance of conservative political ideology to national attachment, we present our core models predicting the Nationalism and U.S. Pride scales here restricted to the 1996 subsample of respondents who provided valid responses for both political ideology and the dependent variables.
